DIAGNOSTIC VALUE OF MRI IN INFLAMMATORY MYOSITIS

OPEN

A 65-year-old woman presented with a 5-week history of generalized weakness and myalgia. She had a history of seropositive myasthenia gravis post thymectomy for invasive thymoma and was in pharmacologic remission on prednisone and methotrexate. Although limited by significant pain, examination showed diffuse proximal and distal weakness. Serum creatine kinase (CK) was 572 IU/L. Myositis antibody panel was negative. MRI of her left extremities showed patchy muscle edema and inflammation (figures 1 and 2). Given the history of myasthenia gravis and thymoma, diagnosis of granulomatous myositis was made.¹ Increased doses of prednisone and methotrexate resulted in resolution of pain and weakness and normalization of CK levels (51 IU/L).

From the Department of Neurology, University of California, Irvine.
Author contributions: Tim Tien Lai: drafting and revising the manuscript, acquisition of figures. Tahseen Mozaffar: drafting and revising the manuscript, study concept or design, interpretation of data.
Study funding: No targeted funding reported.

Disclosures: T.T. Lai reports no disclosures. T. Mozaffar serves on medical and scientific advisory boards for the Myositis Association, Genzyme Genetics, Idera Pharmaceuticals, and Ultragenyx; received travel reimbursement for advisory board meetings from Genzyme Corporation, Biomarlin, and Amicus; has consulted for Amicus, Biomarlin, Genzyme, Sarepta, and Ultragenyx; and received research support from Abhyam, Alexion, Amicus, Biomarlin, CSL, Genzyme, ISIS, GSK, Novartis, Ultragenyx, and NIH.
