Abstract

Objective
To test the hypothesis that antidrug antibodies (ADAs) against alemtuzumab could become relevant after repeated treatments for some individuals, possibly explaining occasional treatment resistance.

Methods
Recombinant alemtuzumab single-chain variable fragment antibody with a dual tandem nanoluciferase reporter linker was made and used to detect binding ADAs. Alemtuzumab immunoglobulin G Alexa Fluor 488 conjugate was used in a competitive binding cell-based assay to detect neutralizing ADAs. The assays were used to retrospectively screen, blinded, banked serum samples from people with MS (n = 32) who had received 3 or more cycles of alemtuzumab. Lymphocyte depletion was measured between baseline and about 1 month postinfusion.

Results
The number of individuals showing limited depletion of lymphocytes increased with the number of treatment cycles. Lack of depletion was also a poor prognostic feature for future disease activity. ADA responses were detected in 29/32 (90.6%) individuals. Neutralizing antibodies occurred before the development of limited depletion in 6/7 individuals (18.8% of the whole sample). Preinfusion, ADA levels predicted limited, postinfusion lymphocyte depletion.

Conclusions
Although ADAs to alemtuzumab have been portrayed as being of no clinical significance, alemtuzumab-specific antibodies appear to be clinically relevant for some individuals, although causation remains to be established. Monitoring of lymphocyte depletion and the antidrug response may be of practical value in patients requiring additional cycles of alemtuzumab. ADA detection may help to inform on retreatment or switching to another treatment.

MS is an immune-mediated, demyelinating disease of the CNS. Memory T and B lymphocytes are key in the pathophysiology of MS, and these cell types are targeted by an increasing number of disease-modifying treatments (DMTs) capable of inhibiting relapsing MS. These DMTs are administered continuously or given as a pulsed immune reconstitution therapy to produce long-term disease inhibition. Alemtuzumab was the first biological immune reconstitution therapy licensed for the treatment of people with MS (PwMS). This depletes lymphocytes in vivo and in vitro by a number of mechanisms, including complement fixation and antibody-dependent cellular cytotoxicity, and has been shown to be highly efficacious in suppressing relapses in PwMS (Comparison of Alemtuzumab and Rebif Efficacy in Multiple Sclerosis Study One and Two [CARE MS I and II]). However, a small number of people appear to be unresponsive to alemtuzumab and continue to experience clinical relapses despite treatment.

Although alemtuzumab was the first humanized monoclonal antibody engineered with the aim of reducing immunogenicity to the founding rodent molecule, surprisingly, it is one of the most immunogenic therapeutic proteins generating antidrug antibodies (ADAs), which may be either binding or neutralizing. Yet, these have been reported to be of minimal clinical significance. Indeed, the dosing schedule of alemtuzumab avoids issues of ADA, which occur with high frequency (~85%) within 2 years of treatment. Using the currently recommended treatment schedule, the infusion cycle ends before primary and secondary antibody responses will be generated, and the recommended interval of at least 12 months between treatment cycles allows ADA levels to subside. Neutralizing ADAs were not mentioned in the pivotal trial reports. Only occurred in 0.6% of PwMS before the second infusion cycle, so would be infrequently problematic within the original 2-year treatment cohort. However, as additional treatment cycles were shown to be efficacious in people not adequately responding to 2 cycles, the European Medicines Agency supported the use of third and fourth treatment cycles in 2017. Hence, predose binding and neutralizing ADA become far more prevalent following the second treatment cycle (75% and 31% at 24 months, respectively), a factor which may limit the biological and clinical efficacy of the subsequent treatment cycles. In this study, we investigated the hypothesis that ADAs become increasingly problematic after successive cycles of alemtuzumab treatment and that the ADA levels may be associated with diminished treatment effectiveness.

Methods

ADA assays
To monitor PwMS in our care, we developed an in-house luminescence-based, antiglobulin detection assays for binding anti-alemtuzumab-specific antibodies. In brief, a recombinant single-chain variable fragment fragment based on alemtuzumab variable heavy and light chains was engineered as a fusion protein with 2 nanoluciferase reporter domains (GloBody). In the presence of ADAs, GloBody-ADA complexes form which are captured on immobilized protein-G and the retained luciferase activity measured. In addition, competitive binding of Alexa Fluor 488-labeled alemtuzumab to adherent human CDS2-expressing Chinese hamster ovary cells, coupled with serial dilutions of serum, was used as a neutralizing assay. Detailed methodology has been reported previously. Ethical approval
Samples were collected with informed consent and ethical approval (Research Ethics Committee approval references: 19/WA/0058 and 05/WSE01/11).

Alemtuzumab treatment
People received 5 daily 12 mg infusions at baseline and 3 daily 12 mg infusions where administered 12 months later. Following disease activity (typically ≥1 relapse and/or ≥2 unique lesions defined as either new/enlarging T2 hyperintense and/or gadolinium-enhancing brain and/or spinal cord lesions via MRI), additional cycles of 3 daily 12 mg infusions could be administered at least 12 months apart.

Samples
The assays were applied to bioarchived serum samples from 32 PwMS who had all received 3 or more cycles of alemtuzumab. Samples were obtained from the Welsh Neuroscience Research Tissue Bank (WNRTB) and had been donated as part of a long-running population study of MS, which has previously been described. Analysis of ADA was performed blinded to clinical and laboratory data from the WNRTB. Individuals had received 3 (n = 24), 4 (n = 3), 5 (n = 4), or 6 (n = 1) cycles of alemtuzumab. Absolute lymphocyte counts, taken from routine laboratory reports where available, from time points immediately before, and 1–2 month after each infusion, were used to calculate relative depletion rates. Apparent lymphocyte depletion was defined as ≥ 35% reduction in absolute lymphocyte count pre- to postinfusion and/or depletion below the lower limit of normal.
Statistical analysis was performed using the t test/Mann-Whitney U tests using Sigmaplot Software (Systat, San Jose, CA).

Results
Cohort characteristics
At the time of sample requisition from the WNRTB, 137 people had received alemtuzumab within the South Wales cohort. In total, 40 people had received 3 or more treatment cycles of alemtuzumab. The rates of receiving a third (or subsequent treatment) in this cohort was 49% (39/80) of people followed up to 5 years and 50% (15/30) of people followed up to 10 years. Archived blood samples were available from 32 of the total 40 individuals who had ever received a third cycle of treatment. The 32 people who had donated blood samples were 28 female (88%) and had a mean age at MS onset of 29 years (range 10–44 years). All PwMS received alemtuzumab as first-line treatment; the first cycle was administered after a mean duration of 4.5 years (range 0.6–17 years) from symptom onset.

Individuals do not deplete lymphocytes on repeated infusion of alemtuzumab
Lymphocyte depletion data were available for 32 of 32 (cycle 1), 32 of 32 (cycle 2), and 31 of 32 (cycle 3). At the population level, lymphocyte depletion was marked and significant ($p < 0.001$) compared with precycle treatment levels for cycle 1 to cycle 3 (figure 1). However, at an individual level, 31 of 32 people (97%) showed apparent lymphocyte depletion following cycle 1, 30 of 32 (94%) after cycle 2, and 27 of 31 (87%) after cycle 3 in PwMS (figure 1). Of the 4 people who did not show apparent lymphocyte depletion after cycle 3, 2 had previously shown limited depletion after cycle 2. Lymphocyte subset analysis was not available. Although it is recognized that these counts will reflect a composite of depleted and repopulating cells, whose composition may change due to the different reconstitution kinetics of distinct lymphocyte subsets, relative lack of depletion may be an indicator for the lack of efficacy of alemtuzumab due to antibody neutralization.

ADA responses occur with high frequency
Baseline serum samples were available for 17/32 PwMS. Using a binding ADA assay, low titers $751 \pm 1,399$ Lux were evident in subjects before the first infusion (figure 2). However, 29/32 (90.6%) people generated binding ADA with a titer $> 2$ SDs above the baseline mean ($>3,549$ Lux) during their subsequent follow-up (figure 2). Some people demonstrated very high ADA titers (mean $1,288,805 \pm 2,773,146$ Lux with a range $1,296–9,965,386$ Lux) following alemtuzumab treatment (figures 2 and 4). A standard monoclonal anti-alemtuzumab immunoglobulin G (Bio-Rad HCA-199) spiked into control serum at $\mu$g/mL generated a signal of $21,159 \pm 6,468$ Lux. The maximum blood concentration range of alemtuzumab immediately after the third infusion is $2.3 \pm 0.8$ $\mu$g/mL; ADA values in the range of the spiked standard would be theoretically at least 16-fold molar excess of the circulating levels of the drug.

Relationship between lymphocyte depletion, ADAs, and treatment response
ADAs were clearly present in 6/7 individuals before poor depletion occurred. Binding ADA titers were boosted with each cycle of treatment, and the binding ADA became persistent in some individuals (figure 3, A–D). This was associated with increasing levels of antibody neutralization (figure 3, A–D). One individual appeared to demonstrate limited lymphocyte depletion despite an absence of neutralizing ADA (figure 3E). However, in this case, month 1
postinfusion lymphocyte data were unavailable. Lymphocyte levels were first measured more than 2.5 months postinfusion, so we cannot exclude the possibility that depletion, followed by rapid repletion, occurred within this time window. Six of 7 individuals who depleted poorly exhibited disease activity within 2 years of infusion. In contrast, it was evident that only 13/28 PwMS with apparent lymphocyte depletion demonstrated disease activity after 3 cycles, with 14/16 people without disease activity having ≥5 years of follow-up. People receiving 4 cycles (figure 3 n = 7/7) of alemtuzumab subsequently exhibited disease activity in this cohort. This study was not designed to monitor the clinical significance of antibody neutralization. However, when comparing baseline and 5-year Expanded Disability Status Scale (EDSS) scores, those who neutralized the alemtuzumab response after 3 cycles of treatment showed a median 1.0 point EDSS worsening (range 0.5–2.0, n = 5), whereas those who did not develop neutralizing antibodies showed a median improvement of 0.5 EDSS points (range −2.0 to 2.5, n = 26). This may suggest that antibody neutralization has clinical significance, but further studies are warranted.

**Predose ADA responses may detect subsequent lymphocyte depletion responses**

As it is known that most people generate ADA that wanes over time (figure 3, B–D),7,8,14 precycle ADA levels and the subsequent lymphocyte depletion level will be most informative on the significance of ADA.7,8 However, only 23 serum samples from 19 different individuals with lymphocyte depletion data were taken less than 2 months before infusion. This included 5 predose samples from poor-depleting individuals whose ADA titers were $2.7 \times 10^6$, $2.8 \times 10^5$, $8.9 \times 10^4$, $1.2 \times 10^5$, and $1.0 \times 10^6$ Lux units (figure 3). Many people who depleted lymphocytes exhibited low-titer (below $1.5 \times 10^3$ Lux units) antibody responses (figure 4A); however, there were individuals who had relatively high titers ($5.8 \times 10^6$ and $1.1 \times 10^5$ Lux units) of binding ADA but exhibited notable depletion (1.4–0.2, 1.8 to 0.4 cells $10^9$/L. Figure 4A) and did not relapse for at least 4 and 7 years after infusion. However, these individuals did not exhibit neutralizing potential (figure 4, B and C). Therefore, binding (<15,000 Lux) and neutralizing (≥10 titer for virtually complete neutralization) titers perhaps could be adopted to suggest poor depleters and depleters (figure 4A). It remains to be established whether this can be applied prospectively, but the data suggest that it is possible that predose ADA titer limits may be set that can exclude potential futile treatments.

**Discussion**

Alemtuzumab is a potent immune reconstitution therapy; however, up to 40%–50% of people receiving alemtuzumab for MS require 3 or more cycles of treatment.5,15 Third and subsequent cycles are often followed by a sustained remission of disease activity,4,15 but cases are recognized to occur where people are unresponsive to alemtuzumab and continue to experience clinical relapses despite treatment. During the clinical development of alemtuzumab, the effect of neutralizing antibodies was not mentioned, and ADAs have been repeatedly portrayed as being clinically insignificant.11,12,19

However, our study suggests that some people develop persistent neutralizing antibody responses to alemtuzumab and that this is associated with limited lymphocyte depletion and disease activity. Although it is not possible to prove cause and effect, it seems likely that high-titer neutralizing responses would blunt or inhibit the lymphocyte depletion response. In this study, 6/32 (18.8%) developed high titers of both binding and neutralizing ADAs and showed subsequent evidence of relative lack of lymphocyte depletion. This is aligned with other reports in the literature of disease activity requiring further infusions associated with lack of lymphocyte depletion, which prompts switching to another DMT.20 However, there are alternative explanations to explain poor depletion and disease breakthrough, such as alemtuzumab treatment leading to the emergence of CD52-negative lymphocytes.21,22 This may have contributed to poor depletion despite limited ADA response in 1 individual. Furthermore, pharmacogenomics, such as Fc receptor genetic variants, linking to antibody-dependent cellular cytotoxicity, may also be relevant, particularly if antibody titers become limiting.1,23–25

Although the precise molecular mechanisms that cause the formation of ADA remain to be defined, it is evident that the majority of people produce CD52-specific ADA following alemtuzumab infusion.7,13 This probably relates to a number of factors that include the dose, dosing schedule, biology of alemtuzumab, CD52 expression profile, and the repopulation kinetics of ADA forming cells and CD52-expressing regulatory subsets.26 These ADAs are boosted with an increasing number of infusions such that they become relatively persistent in some individuals.7,13 Further prospectively collected

Figure 3 Alemtuzumab neutralizing responses appear before PwMS apparently fail to deplete lymphocytes

The (A.a–E.a) binding and (A.b–E.b) neutralizing responses of 5 individuals treated with alemtuzumab. (A.a–E.a) The results show the time of the beginning of each alemtuzumab infusion cycle, the absolute lymphocyte numbers, and the binding ADA titer or the neutralizing responses. (A.a–E.a) Lower limit of normal of lymphocyte number (dashed line). In (A.b–E.b), samples 1–6 or 1–4 are from the same individual at sequential time points during follow-up. Year 0 indicates 1 January of the year of the initial dosing and the time of treatments and sampling during the year are indicated. ADA = antidrug antibody; PwMS = people with MS.
data may help to validate and extend our findings and identify the important perturbations of the immune networks that facilitate ADA formation. Importantly, reevaluation of samples and data from CARE-MS and their extension studies, which contains immunophenotyping and ADA data, may provide further valuable insights into the relationship between both binding and neutralizing (inhibitory) antibody titers and the associated laboratory/clinical data. This may be particularly enhanced if events within lymphoid tissues can be also monitored, as they are the probably the source of ADA-forming cells and are likely to deplete and repopulate differently to the peripheral blood. Previous reports of a lack of association between ADA and lymphocyte depletion at the population level are misleading because population analyses are insensitive to low frequency events, as demonstrated here. The influence of neutralizing ADAs alone has yet to be reported from the pivotal trial extension data, but people with the highest quartile of predose ADA producers deplete their lymphocytes postdose less efficiently than people in the lower 75% percentile, and suggests that analysis of the neutralizing response may be informative for treatment response in some individuals. Therefore, the neutralizing ADA data from the pivotal trial extension studies should be reported. Future work may also further define levels of ADAs that are predictive of disease activity.

The lack of general awareness of the potential of alemtuzumab to induce neutralizing antibodies, coupled with the suggestion that disease activity is not related to lymphocyte levels, may contribute to viewing lymphocyte depletion data as being unimportant. However, a failure of lymphocyte depletion is likely to imply that alemtuzumab is less effective. Once an individual failed to deplete, this was often seen in subsequent treatment cycles. Although it will be the case that only a small
subset of lymphocytes will be clinically important and these will not be accurately monitored by simply measuring lymphocyte numbers, a lack of absolute lymphocyte depletion should prompt extra vigilance.

Our study provides important preliminary data that pre-infusion binding ADA titers >15,000 and/or complete neutralization at >10 fold dilution may be associated with poor postinfusion lymphocyte depletion. Furthermore, this appears to be a predictor for future disease activity and the need for further alemtuzumab infusions. Therefore, monitoring ADA before the second or subsequent infusion cycles may be valuable in guiding treatment decisions. The ADA detection technology used here could also be applied to other monoclonal antibody treatments to inform whether to retreat or to switch therapy. Identifying people who are at risk of ineffective treatment responses might save them from undergoing an expensive and futile treatment and ensure cost-effective use of alemtuzumab.
