Abstract

Background and Objectives
The relationship between smoking, long-term brain atrophy, and clinical disability in patients with multiple sclerosis (MS) is unclear. Here, we assessed long-term effects of smoking by evaluating MRI and clinical outcome measures after 10 years in smoking and nonsmoking patients with relapsing-remitting MS (RRMS).

Methods
We included 85 treatment-naive patients with RRMS with recent inflammatory disease activity who participated in a 10-year follow-up visit after a multicenter clinical trial of 24 months. Smoking status was decided for each patient by 2 separate definitions: by serum cotinine levels measured regularly for the first 2 years of the follow-up (during the clinical trial) and by retrospective patient self-reporting. At the 10-year follow-up visit, clinical tests were repeated, and brain atrophy measures were obtained from MRI using FreeSurfer. Differences in clinical and MRI measurements at the 10-year follow-up between smokers and nonsmokers were investigated by 2-sample t-tests or Mann-Whitney tests and linear mixed-effect regression models. All analyses were conducted separately for each definition of smoking status.

Results
After 10 years, smoking (defined by serum cotinine levels) was associated with lower total white matter volume ($\beta = -21.74, p = 0.039$) and higher logT2 lesion volume ($\beta = 0.22, p = 0.011$). When defining smoking status by patient self-reporting, the repeated analyses found an additional association with lower deep gray matter volume ($\beta = -2.35, p = 0.049$), and smoking was also associated with a higher score (higher walking impairment) on the log timed 25-foot walk test ($\beta = 0.050, p = 0.039$) after 10 years and a larger decrease in paced auditory serial addition test (attention) scores ($\beta = -3.58, p = 0.029$).
Smoking is a known negative prognostic factor in patients with multiple sclerosis (MS), associated with higher disability and higher risk of conversion to progressive disease phenotypes. The causal relationship between these associations is not clear, and several pathophysiologic mechanisms have been proposed, for example: cigarette smoke triggering a proinflammatory cascade, inducing autoimmunity and heightened inflammatory activity; facilitating entry of immune cells to the CNS by disruption of the blood-brain barrier (BBB); epigenetic changes; and direct neurotoxicity due to mitochondrial damage.

Studies examining the relation between smoking and inflammatory disease activity have reported inconsistent findings. Although some studies found smoking to be associated with higher relapse rates and lesion loads, 2 studies using cotinine, an alkaloid metabolite of nicotine, to define smoking status, did not.

In MS, smoking has cross-sectionally been shown to be associated with lower total brain volume but longitudinal relationships have been less well studied and with varying results. Furthermore, few studies have considered the relation between smoking and gray matter (GM) atrophy, again with conflicting results.

To better understand the possible adverse prognostic effects of smoking in MS, we aimed to investigate the relation between smoking and long-term brain lesion load, atrophy, and clinical outcome measures, first by comparing smokers and nonsmokers, defined by both patient self-reporting and cotinine levels, and second by studying a possible dose effect, using mean cotinine levels in smoking patients with MS.

**Discussion**

Smoking was associated with brain atrophy and disability progression 10 years later in patients with RRMS. The findings imply that patients should be advised and offered aid in smoking cessation shortly after diagnosis, to prevent long-term disability progression.

**Standard Protocol Approvals, Registrations, and Patient Consents**

The OFAMS-study and the 10-year follow-up were approved by the Regional Committee for Medical and Health Research Ethics in Western Norway Regional Health Authority (OFAMS-study: clinicaltrials.gov, Identifier: NCT00360906). All participants gave their written informed consent.

**Cotinine Measurement**

Serum samples were stored at −80°C until analysis and performed simultaneously for all samples from each patient. As previously described, serum cotinine levels were measured by liquid chromatography tandem mass spectrometry at Bevital AS (Bergen, Norway). Laboratory technicians were blinded to patient clinical status. Serum cotinine levels were analyzed from samples collected during the OFAMS-study at baseline (BL) and months 6, 12, 18, and 24.

**Definitions of Smokers and Nonsmokers**

The effect of smoking status on long-term MRI and clinical outcome measures was analyzed using 2 definitions (described below) of smoking status separately: by (1) serum cotinine levels, with the findings presented in the main text and (2) patient self-reporting, with the findings presented in the supplemental material.

**Smoking Defined by Cotinine Levels**

Cotinine levels >85 nmol/L indicate recent tobacco use and are regarded to distinguish tobacco users from nontobacco users in the general population. Patients were categorized into 2 groups according to serum cotinine level: smokers were defined as patients with serum cotinine level >85 nmol/L in ≥60% of the samples and nonsmokers were defined as patients with serum cotinine levels ≤85 nmol/L in ≥60% of the samples. Based on previous studies not finding nicotine or smokeless tobacco to be associated with MS disease progression, patients who at the 10-year follow-up visit...
reported “snuff” use (oral tobacco), but no smoking for the past 10 years, were defined as nonsmokers (Figure 1).

Smoking Defined by Patient Self-Reporting
At the 10-year follow-up visit, patients answered a questionnaire about habits of tobacco use, including smoking and snuff use. Patients who reported to have smoked regularly within the past 10 years were defined as smokers while patients who did not report regular smoking, or reported only snuff use (6 patients), were defined as nonsmokers (Figure 1).

Risk Factors and Presence of Peripheral, Cardiovascular, or Cerebrovascular Disease
Vascular risk factors and established peripheral, cardiovascular, and cerebrovascular disease are independently associated with brain imaging changes.20 As smoking is a known risk factor for such conditions,21 patient-reported hypertension, dyslipidemia, hypercoagulable disorder, and symptomatic cardiovascular or cerebrovascular disease and/or events was designated as a dichotomous vascular disease (VD) factor and included as a covariate in the final analyses.

MRI Data and Analysis
The 10-year Follow-up Visit
Imaging was performed at the different study sites, on a 3 Tesla (T) MRI scanner if available, alternatively using a 1.5T MRI scanner, with a standard head coil. The acquisition protocol included the following MRI sequences: a T2-weighted 3D sagittal fluid attenuated inversion recovery (FLAIR) (resolution: 1 × 1 × 1 mm3, echo time (TE)/repetition time (TR)/inversion time (TI) = 386/5000/1.65–2.2 ms) and a postcontrast T1-weighted 3D sagittal magnetization-prepared rapid gradient echo sequence (resolution: 1 × 1 × 1 mm3, TE/TR/TI = 2.28/1800/900 ms, flip angle 8°). Acquisition details across sites are presented in eTable 1, links.lww.com/NXI/A728.

Lesion Segmentation
Lesion segmentation was performed on FLAIR images using lesion segmentation tool (version 2.0.15; applied-statistics.de/lst.html).22 To optimize lesion filling, gadolinium-enhancing regions (both lesions and other regions) were first removed, by applying an upper intensity threshold at the 98th percentile. Next, the FMRIB Software Library (version 5.0.10) was used to fill in abnormal voxels in these preprocessed T1-weighted images using the lesion_filling tool.24 Then, only the filled lesion voxels were pasted back into the original postcontrast 3D T1-weighted images to create the final lesion filled images.

Morphological Reconstruction
Cortical reconstruction and parcellation for (local) cortical volume and thickness measurement and subcortical segmentation were performed with FreeSurfer version 7.1.1, a freely available software package for academic use, available through online download.25 The technical details of FreeSurfer procedures have been previously described.26,27 The use of FreeSurfer on postcontrast 3D T1-weighted images as applied here, was recently validated.28
Quality control was performed by visual inspection, discarding cases with large segmentation errors. Minor to moderate segmentation errors of specific anatomic regions were found in all scans and are previously shown to occur more frequently and to a more severe degree in postcontrast images. We chose to not apply any manual corrections for these errors in our analyses. The Desikan-Killiany atlas was used to extract cortical thickness measures. The mean cortical thickness of the left and right hemisphere was averaged to calculate the overall mean cortical thickness. Furthermore, total cerebral GM and white matter (WM) volume and total deep GM and thalamus volume (average of left and right hemisphere) were obtained. Because of frequent suboptimal segmentation of the temporal pole (previously found in a minor to moderate degree in almost 50% of postcontrast scans), this region was excluded when calculating the total GM volume.

Statistical Analysis
Statistical analyses were performed using Statistical Product and Service Solutions (SPSS) for macOS (Version 25; SPSS, Chicago, IL) and R software (V.4.0.5).

Kolmogorov-Smirnov tests and visual inspection of the histograms were used to assess the normality of the variables.

As a first exploratory analysis, the difference in outcome measures between smokers and nonsmokers was analyzed by 2-sample t tests for normally distributed variables; otherwise, Mann-Whitney tests were used.

The relationship of smoking status and mean cotinine level with MRI and clinical outcome measures was then further investigated by a linear mixed-effect regression model, correcting for age, sex, vascular disease, estimated total intracranial volume (eTIV) (eTIV included as a covariate in analyses regarding brain volume measurements), BL EDSS, and time from diagnosis. To correct for scanner variability, MRI scanner was entered as a random effect. Assumptions for linear regression were checked for each final model; if the assumptions were not satisfied, log-linear transformation was performed (e.g., logT2 lesion volume). For variables with values below 1, a constant was added before log transformation.

Data Availability

Results
Patient Characteristics
We included the 85 patients who participated in the 10-year follow-up. Each patient was classified as a smoker or nonsmoker, by the 2 different definitions of smoking: (1) by cotinine levels measured during the OFAMS-study and (2) by retrospective patient self-reporting at the 10-year follow-up.
(Figure 1). Samples available for cotinine analyses were missing for one patient, and another patient did not complete the questionnaire concerning tobacco use, leaving 84 patients to be classified as smoker or nonsmoker by each definition. Including the 2 patients missing either cotinine measurements or the questionnaire, 9 patients were classified differently based on the 2 definitions. Forty-seven patients were smokers and 37 nonsmokers defined by cotinine levels. By patient self-reporting, 48 patients were smokers and 36 nonsmokers. Of the 48 smokers defined by patient self-reporting, 47 reported to smoke 10 years ago. Additional patient self-reported smoking habits are listed in supplemental eTable 2, links.lww.com/NXI/A728.

The mean follow-up time from the BL and month 24 visit to the 10-year follow-up visit was 12.0 (±0.6) and 10.0 (±0.6) years, respectively. Table 1 summarizes the clinical characteristics of the included patients.

**Smoking Status and Long-term MRI and Clinical Outcome Measures**

The results from the linear mixed-model investigating the relationship between smoking and long-term MRI and clinical measures are shown in Table 3 (smoking defined by cotinine levels) and supplemental eTable 4, links.lww.com/NXI/A728 (smoking defined by patient self-reporting). Smoking defined by cotinine level was associated with lower total WM volume (β = −21.74, p = 0.039) after 10 years and with higher total logT2 lesion volume (β = 0.22, p = 0.011). Similar results were found for smoking defined by patient self-reporting (eTable 4), additionally associated with lower deep GM volume (β = −2.35, p = 0.049) after 10 years. There were no significant associations between smoking and clinical disability when
defined by cotinine levels (Table 3), but when defined by patient self-reporting, smoking was associated with a higher score on the logT25FW test ($\beta = 0.050$, $p = 0.039$) after 10 years and a larger decrease in PASAT scores ($\beta = -3.58$, $p = 0.029$) (eTable 4).

**Discussion**

We found that patients with MS who smoked had lower total WM and deep GM volumes and higher T2 lesion volumes after 10 years. Smokers also accumulated more disability and incurred a larger decrease in attention scores measured by the T25FW and PASAT test, respectively. The results obtained by defining smokers by cotinine levels collected during the initial 2-year period were highly comparable with those obtained when defining smokers by retrospective patient self-reporting. Furthermore, the associations were still significant when correcting for vascular risk factors and established cardiovascular disease. These findings suggest that smoking has a negative long-term influence on prognosis and disease progression in patients with MS.

The association between smoking and higher lesion load is partly in line with previous research, supporting the notion that smoking could heighten inflammatory activity. However, smoking and increased lesion activity have not been consistently related, as also shown in a previous study investigating the same patient cohort as in this current work. In the previous study, no association was found between tobacco use (defined by cotinine levels) and the occurrence of new or enlarging lesions during the trial period of 24 months. The discrepant findings in this same study population may be a result of the different outcome measures used, that is, lesion volumes vs the less sensitive dichotomous measure of new or expanding lesions present or not present, especially considering the more limited follow-up time of 2 years. Moreover, it is unknown how smoking may affect pathologic processes within the occurring lesions. Lesions with persistent subtle inflammation, called chronic active or smoldering lesions, are associated with low-grade BBB leakage, higher atrophy rates, and have been shown to develop in patients with RRMS and slowly expand over years. In this study, we were unable to investigate whether smokers had a higher fraction of smoldering lesions, but testing that hypothesis could provide insight to the discrepant associations found for the occurrence of new lesions and total lesion volume and to the overall worse prognosis seen in smoking patients with MS.

After 10 years, we found that deep GM and total WM volume were lower in patients who smoked. Previous longitudinal studies on smoking/nonsmoking patients with MS have mainly assessed whole-brain atrophy and have not reported consistent results. Cross-sectional studies assessing GM atrophy showed a similar lack of consensus. In studies investigating non-MS populations, smoking is associated with atrophy most evidently in the frontal and temporal lobe, cingulate gyrus, and the cerebellum, while the associations with subcortical GM are more variable. Furthermore, neither studies on MS nor those on non-MS populations have found smoking to be related to lower WM volume. In early MS, atrophy in the deep GM has previously been shown to develop at a relatively high rate compared with other GM regions, and to be closely related to WM lesions. Although the causal mechanisms are still not sufficiently clear, a spatiotemporal relationship between WM lesions and subsequent deep GM atrophy progression through neuroaxonal degradation seems likely, explaining at least part of the neurodegenerative process. Together with the higher lesion volume, our findings of lower deep GM and total WM volumes in smoking patients with MS may suggest that the pathologic changes are driven by increased inflammatory damage in the WM, followed by secondary degeneration in regions either consisting of WM or highly connected through
Sclerosis Severity Score in cross-sectional analyses, but the relation between smoking and higher EDSS or Multiple Sclerosis Severity Score over the follow-up has previously been reported in this current patient population. In our study, we concluded on atrophy progression in smoking patients with MS.

Our study is not without limitations. Brain atrophy and lesion load were measured cross-sectionally at the 10-year follow-up visit. In future research, long-term measurements should be corrected for values at baseline if available, or be investigated by longitudinal analyses, to conclude on atrophy progression in smoking patients with MS.

Obtaining volume and cortical thickness measures in postcontrast images by FreeSurfer is not the standard approach. Recent work using data from a subgroup of this patient cohort has demonstrated excellent consistency between values obtained from precontrast and postcontrast 3D ‘T1-weighted images, although minor to moderate segmentation errors, especially in the temporal lobe were more common in postcontrast images. In this current study, we did not apply manual corrections for these errors, and the volume of the temporal lobe was excluded from the total GM volume to limit the possible bias introduced by the larger variability in measurements extracted from this region. In future studies, corrections of these segmentation errors should be considered, especially if evaluating regional atrophy measures.

Owing to its stability in plasma over time (half-life of approximately 20 hours), cotinine has become the preferred biomarker to quantify long-term nicotine exposure. However, the use of cotinine levels as a proxy for smoking is potentially biased by other sources of nicotine. This is an important limitation because neither nicotine nor smokeless tobacco have shown to induce inflammation in MS or increase the risk of the disease. In our study, patients who at the 10-year follow-up reported use of smokeless tobacco (e.g., snuff) exclusively (4 patients) were, therefore, classified as nonsmokers, regardless of their measured cotinine levels. Furthermore, the results obtained by defining smoking by
cotinine levels were comparable with those using patient self-reporting to define smoking habits. The associations with MRI atrophy and clinical measures were somewhat stronger when using the definition based on patient self-reporting, most notably for clinical disability. This may be explained by this definition also capturing patients who smoked regularly in time periods during the follow-up, after the 2 years of the clinical trial. In this study, serum cotinine measurements were not available after the first 2 years of follow-up or at the 10-year follow-up visit. In future works, the effect of cotinine levels measured regularly over a longer follow-up period should be explored, especially to determine the effect of smoking duration and cessation. Nevertheless, the overall comparable results suggest that serum cotinine levels provide an objective and reliable option for defining smoking habits and especially to investigate dose-dependent relationships.

Several comorbid conditions may independently influence brain tissue changes (including gray and WM atrophy and localized WM hyperintensities) and can be caused or exacerbated by smoking. Smoking was associated with lower deep GM and total WM volume and higher T2 lesion volume after 10 years in patients with RRMS. Patients who smoked had higher physical and cognitive disability accrual, measured by the T25FW and PASAT test, respectively. The findings suggest that smoking patients with MS should be advised and offered aid in smoking cessation as early as possible in the disease course.
